## Layering Predictions: Flexible Use of Dialog Expectation in Speech Recognition

### Sheryi R. Young, Wayne H. Ward and Alexander G. Hauptmann January 1989 CMU-CS-89-105

#### Abstract

When computer speech recognition is used for problem solving or any plan based task, predictable features of the user's behavior may be inferred and used to aid the recognition of the speech input. The MINDS system generates expectations of what will be said next and uses them to assist speech recognition. Since a user does not always conform to system expectations, MINDS handles violated expectations. We use pragmatic knowledge to dynamically derive constraints about what the user is likely to say next. Then we loosen the constraints in a principled manner. We generate layered sets of predictions which range from very specific to very general. To enable the speech system to give priority to recognizing what a user is most likely to say, each prediction set dynamically generates a grammar which is used by the speech recognizer. A different set of grammars is created after each user utterance. The grammars are tried in order of most specific first, until an acceptable parse is found. This allows optimal performance when users behave predictably, and displays graceful degradation when they do not.

### 1. Overview

One of the biggest problems in computer speech recognition is coping with large search spaces. As search space size decreases, recognition performance increases. Most current speech recognizers use some form of syntactic and semantic knowledge to constrain the search space. Only utterances that are semantically and syntactically acceptable are searched for in the input speech signal. In a structured task such as problem solving, additional pragmatic knowledge sources are available for constraining search spaces. In these applications, predictive use of constraints derived from problem solving plans and context have been shown to significantly reduce search space and improve recognition [29, 28, 11, 27]. To allow for diverse and unconventional user behavior, we need a principled manner for relaxing contextual constraints when they are violated. In order to do this, we organize constraints into sets that are successively more restrictive, called "layers". When some constraints are violated, we use the non-violated constraints from a less restrictive layer to reduce search space. Additionally, the flexible use of predictions allows us to derive constraints from less reliable knowledge sources. Users that behave consistent with the dynamically derived expectations can benefit greatly from enhanced recognition and the system will show a graceful degradation for those who do not. Finally, the flexible application of constraints derived from pragmatic knowledge sources will become increasingly important as we move toward larger domains and spontaneous speech recognition where search space size increases exponentialy.

In this manuscript we describe an approach for using layered contextual constraints to dynamically circumscribe the search space for words in a speech signal. The implemented system (MINDS) uses these layered constraints to guide the search for words in our speech recognizer. For our recognizer, we use a modified version of the SPHINX [15]large vocabulary, speaker independent, continuous speech recognition system. We describe our algorithm for creating layered predictions and report the results of an experiment to evaluate search space

# 2. Prior Use of Constraints in Speech Recognition

Large search space is a pressing problem in speech recognition. Essentially, speech recognition systems attempt to recognize phonemes or words in a digitized speech signal. Phoneme recognizers must also store patterns for combining the phonemes into words. There are many reasons this is difficult. The same phoneme can be compressed or expanded in time. Its pattern pronounciations. When one considers connected speech, the above problems are further componded by problems in identifying word boundaries and difficulties dealing with word combined and omitted. Speaker independent speech recognition further compounds the pattern speech and have different vocal tract characteristics. Thus, the signal patterns of different words are occasionally more alike than the patterns associated with a single word pronounced by analyze increases.

Knowledge can be used to constrain the exponential growth of a search space and hence increase processing speed and recognition accuracy [19, 6, 13]. For example, the HARPY system [19] achieved a six order of magnitude search space reduction by using a finite state grammar which ensured that no syntactically or semantically inaccurate word sequences were matched in the speech signal.

Currently, the most common approach to constraining search space is to use a grammar. The grammars used for speech recognition dictate legal word sequences. Normally they are used in a strict left to right fashion and embody syntactic and semantic constraints on individual sentences. These constraints are represented in some form of probabilistic or semantic network which does not change from utterance to utterance [14, 3, 13]. A variant on this approach is to emphasize semantic structure over syntactic constraints, as exemplified in caseframe parsing of speech [12].

The work on caseframe parsing provides two important insights into the speech recognition problem. First, the work demonstrates that semantic constraints alone enough constraint to

significantly improve speech. Like other systems emphasizing semantic structure over syntactic constraint [9] this system leaves too much ambiguity in the syntactic combination possibilities and consequently shows poor recognition results. Secondly, the work demonstrates the need to apply constraints earlier in the recognition process than at the parsing level. These system generate word hypotheses (usually in the form of a word lattice) and then use semantic and syntactic constraints to select meaningful sequences of words from the set of all hypothesized words. The bottom up processing of the speech signal input results in the generation of too many word hypotheses for effective parsing. In general, those systems applying knowledge early in the recognition process (to guide the word search) have shown better results.

There are many other knowledge sources besides syntax and semantics. Typically, these are clustered into the category of pragmatic knowledge. Pragmatic knowledge minimally includes inferring plans, using context across clausal and sentence boundaries, determining local and global constraints on utterances and dealing with definite and pronominal reference. Work in the natural language community has shown that pragmatic knowledge sources are important for understanding language. People communicate to accomplish goals [22], and the structure of the plans to accomplish them are well understood [20, 21, 7]. Goals, plans and context are important for understanding implied information, understanding unexpected information and for providing helpful responses [24, 25, 5, 1, 18, 10] [4].

In the past, pragmatic, dialog level knowledge sources were used in speech to either correct speech recognition errors [8, 2] or to disambiguate spoken input and perform inferences required for understanding [17, 16, 14, 23, 26]. In these systems, pragmatic knowledge was applied to the output of the recognizer.

More recently, pragmatic knowledge sources have been used predictively to circumscribe the search space for words in a speech signal [11, 27, 28]. The MINDS system used an elaborate dialog model to infer plans, perform plan tracking, deal with clarification subdialogs and dynamically compute constraints using local and global focus. These knowledge sources were used predictively to dynamically restrict the sequences of words which could be matched in a speech signal. However, the first version of the MINDS system required users to act according to one of the plans known to the system. This worked well as long as the user conformed. There was no strategy for detecting and recovering from violations of these plan based constraints. We have made the system more robust with respect to these violations by introducing the mechanism of "layered predictions".

In the next section we describe the use of plans to limit search space and the algorithms which enable the MINDS system to use a layered set of predictions to dynamically modify the search space for words.

#### **3. Plan Based Constraints**

The idea underlying the MINDS system is that tracking all information communicated (user questions and database answers) enables a system to infer a set of user goals and possible problem solving plans for accomplishing these goals. Additionally, dialog history enables a system to track goal and plan modifications. In the convention of Newell and Simon (1972) these goals and plans are represented as hierarchically organized goal states. For example, in the domain of dealing with disabled ships, a goal state would be finding a replacement ship. As each new input sentence is spoken, the system analyzes the utterance to determine the concepts expressed and uses these concepts to activate goal states. To derive constraints on future utterances, active goal states are assessed to determine legal next states. For example, when finding a replacement ship, some of the legal next states which follow a question about the ships in some region are questions about more ships in the region, questions about availability of these ships, and questions about the ships' equipment. Because speech systems use grammars to guide word transitions, we associated a list of required and optional concepts with each goal state (e.g. concepts associated with a goal state for ship equipment include equipment, weapons, aircraft, electronics, etc.). The list of possible next states is used to generate a set of possible concepts which could be spoken in the next utterance. This set is then limited by local and global focus which takes into account prior context, rules about reference, etc. The speech recognizer only searches for surface forms expressing concepts in this set.

#### **3.1. Layered Predictions**

The constraints described above were quite effective in reducing search space and improving speech recognition performance (Young, Hauptmann and Ward, 1988; Hauptmann, Young and Ward, 1988). However, there were two problems with the approach:

- 1. The system could not deal with unexpected behavior
- 2. As domain size increased, the number of possible goals and plans increased and the constraint decreased.

To deal with these shortcomings, we instituted two system modifications:

- 1. we enabled the system to loosen its constraints by generating layered predictions
- 2. we incorporated additional, less reliable knowledge sources into the predictions mechanism

To overcome the problem of having multiple active goals and plans, we instituted three procedures. First, since it is not possible to uniquely determine which goal state has been "activated" from an incoming utterance, we designed an algorithm to select "the most probable" goal state. Here we preferred goal states that were both complete and most likely to follow given the previous goal states activated, particularly those that were consistent with active goals at higher levels of the hierarchy. Secondly, we maintained a list of all incomplete active goals, including those which were not hierarchically embedded. These active goals were used to generate some alternate predictions about what the user could say. Finally, we used all of our domain knowledge to generate a set of layered predictions about the content of the following utterance. The predictions ranged from very specific to very general. These layered predictions were rank ordered to reflect both amount of constraint as well as what the system felt the user would most likely say. It should be noted that the least constraining prediction layer allowed all domain concepts. This means that the system could cope with any statement the user might say even if its not included in the system grammar<sup>1</sup>.

By layering predictions, we allow the system to reparse a speech signal with a different grammar until such time as a good parse is received. The ability to reparse an utterance also enables us to use less reliable knowledge sources to further constrain our predictions. Hence, we added two additional knowledge sources to the system: user domain expertise models and preference orderings for conjunctive goals.

Observing that system users with significant domain expertise solved problems using very different plans than novice users, we attempted to model the effects of expertise by constructing domain knowledge models of novice, intermediate and expert system users. Our user models were represented as subsets of the domain knowledge base. The models differed primarily by the existence of relations between domain objects. For example, an expert user would know that each class of ships has a set of default equipment and is suited for particular types of tasks, while a novice user might not be aware that shiptypes are divided into ship classes. The user models were then used to construct control schemas which specified which goal states were exclusive. To further the last example, a control schema for an expert user would show that if the user asked about a shipclass they would not ask about default equipment. These models were hand coded from the training set data.

Similarly, we used the training data to derive probabilitistic orderings on conjunctive subgoals. These orderings told us which conjunctive goals would be executed first, second, etc. The orderings were computed across individuals (although our training data only came from two people). However, there is no reason why these could not be automatically obtained for individual system users in future systems.

Thus, the MINDS system used the following knowledge sources to derive predictions about the content of a user's next utterance:

- 1. knowledge of problem solving plans and goals represented hierarchically,
- 2. semantic knowledge about the application domain's objects, attributes and their

<sup>&</sup>lt;sup>1</sup>However, the system cannot cope with words which are not included in the system lexicon

interrelations (a domain knowledge base),

- 3. domain independent knowledge about methods of speaking, appropriateness of references and partial utterances (local and global focus)
- 4. dialog history knowledge about information previously communicated,
- 5. discrete models of user domain expertise as described above, and
- 6. information about user preferences for ordering conjunctive subgoals

These knowledge sources were used by the prediction module to perform iterative analyses of the dialog after each input/database response pair and generate sets of restrictions on the next utterance. The predictions generated are layered. Each successive layer is less constraining than the prior layer. The most constraining prediction set is generated using all knowledge sources listed above. The next set does not use user models and uses a larger non-overlapping set of goal states. Further sets are generated by moving upward in the goal hierarchy, allowing more goals and plans to be executed. The prediction sets become successively more general, hence the term "layered". Ultimately, the entire system grammar will be used. If this fails, an "allword" recognition is attempted where any word sequences are allowed (providing of course that the words are in the system lexicon). As described before, the predictions are used to restrict the surface forms searched for by the recognizer. The system uses these layers by first trying to parse at the most constraining layer. Should the parse fail to exceed a predetermined goodness score, the system reanalyzes the utterance using the next layer of predictions.

#### 4. Derivation of Predictions

Each goal state is represented as a schema, which can be seen in Figure 1.

Figure 1: Example Goal State Schema

```
[ Shipclass
 :Concepts-Required ((Shipclass single-use Child-restrictions*
                                          (knoxclass perryclass)))
                   Concept Times-used Restriction-pointers
 :Optional-Concepts ((Region single-use Child-restrictions*
                                             (Persian-gulf)))
                     (Not for expert-user)
 :Optional
                     True/Nil/User-consideration
                     (Find-Replacement) goal-state
 :Next-states
                     (Find-Replacement)
 :Parent

 :Control
                     (none)
* = Computed by local and global focus
Figure 2: Example Control Schema
```

The concepts-required and optional-concepts slot values are used to specify the concepts relevant when a user transits to the goal state. The number of concepts per goal state and the number of goal states a user could progress to next determine the size of the lexicon the speech recognition system must analyze. The control slot contains a pointer to a control schema wherever the child slot is not empty.

Control schemas predict whether any child states are likely to be omitted and any preferred

orderings on the states for a specific system user. They are used to generate the most constraining prediction layers.

As seen in Figure 2, there are three slots in a control schema. The order slot stores information about preferred orderings among non-optional, conjunctive subgoal states. The exclusive slot stores pairs of goal states which are exclusive because the information in the first allows the user to infer the information in the second. The omit slot store a list of goal states the user omits because they are unaware of the domain concepts.

Control schemas are attached to parent goal states to predict which child states will be visited. Hence, they are also used to dynamically compute the value of the **optional** slot for each child schema. When a state is predicted to be omitted, the optional slot value becomes true for that cycle of input and database response. The **optional** and **concepts-required** slots are important for determining when a goal state is complete.

These structures are used to derive predictions by the following process. When an incoming utterance and database response are processed, we select the most likely set of goals being executed. If a goal is not complete, then our most constraining prediction set reflects the one or more goals are complete, we identify the next goal states to which a system user could transit. Identifying possible next states is the basis for each layer of predictions. Next, we take all of the possible next plan step and goal which would follow from the just completed goal and store them. Following this, we apply our less reliable knowledge sources to further prune the set of next, most likely steps. To do this, we first use any and all knowledge of user ordering information and then on the states which could be omitted. Then, since all goals and possible roblem solving plans are represented in a hierarchical manner, we progressively move up a layer in the hierarchy of active goals to determine the state to which the user could next progress. Once we have determined the next states, we can take the concepts associated with the states and compute restrictions on partial utterances. A more precise summary of the algorithm for generating predictions once a goal node is complete is presented below.

- 1. Find goal's next state (a goal node, usually a parent state), say G<sub>i</sub>
- 2. Assess  $G_i$  to determine which of its subgoals  $(H_j)$  are incomplete and store the incomplete subgoals in a list  $(L_{k1})$
- 3. Assess  $G_i$ 's control schema to determine if any of the  $H_j$ 's in list  $L_{k1}$  are to be omitted or are mutually exclusive with already complete subgoals. If so, create list  $L_{k2}$ , eliminating the appropriate  $H_j$ 's and reformulate  $L_{k1}$  so that it does not intersect with  $L_{k2}$ .
- 4. If there is more that one subgoal in the remaining list (either  $L_{k2}$  if it exists, else  $L_{k1}$ ) create list  $L_{k3}$  by determining which of the  $H_j$ 's is predicted to occur prior to the others. Eliminate this  $H_j$  from the appropriate list.
- 5. For each list, beginning with  $L_{k3}$  if it exists, collect all concepts associated with the state and compute any restrictions on these concepts. Then find the associated grammar networks associated with these concepts and generate a layer of predictions.
- 6. Find  $G_i$ 's parent state and its  $H_j$ 's, exclusive of  $G_i$  and repeat step 5.
- 7. Repeat step 6 until the tree's root node is found.

<sup>&</sup>lt;sup>2</sup>The algorithm is somewhat simplified for purposes of this discussion. A forthcoming paper will discuss predictions re: clarification subdialogs and multiple non-hierarchically embedded active goals

#### 5. Results

The above described use of plans in speech recognition is currently embodied in the MINDS multimedia interactive dialog system. Users can speak, type or point to input information and both the system and the user can initiate clarification dialogs when appropriate. It uses an adapted version of the SPHINX [15] speech regognition system with a 1000 word vocabulary. Its task domain is naval resource management. Here users must query a relational database to determine whether a disabled vessel should be replaced with another vessel, scheduled for a later repair, or whether the mission should be delayed.

To test the ability of our layered predictions to both reduce search space and to imporve speech recognition performance, we used an independent test set. This means that the utterances processed by the system were not used to train either the speech recognition system or the dialog model, user models or ordering preferences. Furthermore, the test set did not include any clarificiation dialogs.

#### 5.1. Test and Training Sets

Our test data (10 scenarios) were adapted versions of three problem solving sessions taken from the TONE database. The TONE database is a set of speech transcripts from Naval personnel solving problems about what to do with a disabled vessel. The personnel must determine whether to delay a mission, find a replacement vessel or schedule a repair for a later date. They use a database to find necessary problem solving information. In addition to the three scenarios from the TONE database, we created seven additional sessions by paraphrasing the original three. These scenarios were not used to train upon.

Our training data were five different problem solving scenarios from the TONE database. The training scenarios were used for writing grammars and developing user models. Domain goals and problem solving plans were derived from an abstract description of the stages and options available to a problem solver. The abstract plan descriptions were provided by the Navy.

Our database was different from the one used in gathering the TONE transcripts. While it contained the same fields, the information about particular ships differed across the two databases. To enable testing with the TONE transcripts, we had to adapt the test scenarios. Our adaptations consisted of the following:

- Shipnames were changed to correspond to those in our database.
- Lexical entries not in our lexicon (such as 'employment schedule') were replaced with equivalent concepts from our lexicon (such as 'mission' and 'mission importance').
- Database inconsistencies were resolved in favor of the CMU database. For example, if in the naval database, ship X required capability Y for its mission but in the CMU database ship, X required mission capability Z, all references in a scenario to Y were replaced with references to Z.

These adaptations were necessary to evaluate the system without creating a new database and should have minimal impact on the integrity of the data.

## 5.2. Reduction in Search Space

To measure the constraint imposed by the knowledge sources, we use an index called perplexity. This is an information theoretic measure that is widely used in speech systems to characterize the constraint provided by a grammar. Perplexity represents the geometric mean of the number of alternative words at any point. Search space size for a given test sentence is computed by raising perplexity to the number of words in the sentence.

To measure the reduction in perplexity and search space it was necessary to collect test set perplexity measurements for each of the parsed sentences in two conditions:

- Total domain grammar alone
- Using predictions

Test set perplexity is the perplexity of the actual sentence parsed. It is different that total grammar perplexity because it takes into account only those alternatives which are legal next words given the grammar.

To measure the test set perplexity of all the sentences in each of the test scenarios using the entire system grammar is relatively straight forward. However, measuring the test set perplexity of sentences which are parsed with layered predictions is not. Since prediction layers fail, we must report the perplexity of the layers which were successful. However, since some layers are non-overlapping, the number we report is the perplexity of the successful prediction layer merged with all the unsuccessful layers attempted.

As seen in Table 1, test set perplexity was reduced from 279.2 to 17.8.

Reduction in Branching Factor and Search Space			
Constraints used:	grammar	layered predictions	
Test Set Perplexity	279.2	17.8	

### **5.3. Recognition Performance**

To evaluate the effects of using layered predictions on recognition performance we used ten speakers (8 male, 2 female) who had not been used to traing the recognizer. Each speaker read 20 sentences from the adapted version of the three original test scenarios provided by the Navy. Each of these utterances was recorded. The speech recordings were then run through the SPHINX recognition system in two conditions:

- using the system grammar (all legal sentences)
- using the grammar from the successful prediction layer merged with all unsuccessful layers

The results can be seen in Table 2.

Recognition Performance				
Constraints used:	grammar	layered predictions		
Test Set Perplexity	242.4	18.3		
Word Accuracy	82.1	96.5		
Semantic Accuracy	85%	100%		
Insertions	0.0%	0.5%		
Deletions	8.5%	1.6%		
Substitutions	9.4%	1.4%		

As can be seen, the system performed significantly better with the predictions. Error rate decreased by a factor of five. Perhaps more important, however, is the nature of the errors. In the "layered predictions" condition, 89 percent of the insertions and deletions were the word "the". Additionally, 67 percent of the substitutions were "his" for "its". Furthermore, none of the errors in the "layered predictions" condition resulted in an incorrect database query. Because both our database and the Navy's database shared the same fields and were implemented using Informix<sup>TM</sup>, we could directly assess the accuracy of the SQL database queries to Informix. Hence, semantic accuracy, defined as a correct database query, was 100% in the "layered prediction" condition.

5.4. Layers Used Since the results reported above rely upon a small sample of dialogs, we decided to further further evaluate the robustness of our layered predictions using a much larger set of dialogs. Here we employed an independent test set of 20 additional scenarios gathered from 20 different people. These scenarios were collected by a dissertation student using a different population of naval personnel. The transcripts contained spontaneous speech utterances. Since we could not reasonably expect grammatical coverage of this data, we used only the semantic parser output and compared the concepts in the semantic parse with the concepts predicted by the layered predictions. The results are divdied into three categories:

- Semantic content of utterances predicted by knowledge sources above the layer of the most likely next goal states,
- Semantic content of utterance predicted by the most likely goal states
- Semantic content of utterances predicted by user model knowledge sources which further restrict the goal based predictions.

The results can be seen in Table 4.

Percent of Correct Parses by Prediction Layer		
User Level	75% -??	
Best Goal Level	95% -??	
Other Active Goals	100% -??	

#### 6. Summary

The use of layered predictions derived from pragmatic knowledge sources is a very powerful technique for improving speech reocngition. Layered predictions allow the recognition system to capitialize upon pragmatic knowledge sources without impairing their ability to recognize less liekly utterances. The more consistent the users behavior, the better the recognition. As user behavior deviates, recognition accuracy degrades gracefully and the system is capable of recovering and generating further pragmatic predictions based upon both the users expected and less expected behavior.
